ABSTRACT

Short-term synaptic plasticity is found in many areas of the central nervous system. In the inhibitory half-centre central pattern generators involved in locomotion, synaptic depression is believed to act as a burst termination mechanism, allowing networks to generate anti-phase bursting patterns of varying periods. To better understand burst generation in these central patter generators, we study a minimal network of two neurons coupled through depressing synapses. Depending on the strength of the synaptic conductance between the two neurons, this network can produce symmetric $n-n$ anti-phase bursts, where neurons fire n spikes in alternation, with the period of such solutions increasing with the strength of the synaptic conductance. Relying on the timescale disparity in the model, we reduce the eight-dimensional network equations to a fully-explicit scalar Poincaré burst map. This map tracks the state of synaptic depression from one burst to the next and captures the complex bursting dynamics of the network. Fixed points of this map are associated with stable burst solutions of the full network model, and are created through fold bifurcations of maps. We derive conditions that describe period-increment bifurcations between stable $n{-}n$ and $(n{+}1){-}(n{+}1)$ bursts, producing a full bifurcation diagram of the burst cycle period. Predictions of the Poincaré map fit excellently with numerical simulations of the full network model and allow the study of parameter sensitivity for rhythm generation.

Keywords: Synaptic depression, Poincaré map, Dynamical system, Neuronal bursting, Central pattern generator

1 INTRODUCTION

2 MATERIALS AND METHODS

We consider a pair of identical Morris-Lecar neurons [1], with parameters adapted from [2]. The Morris-Lecar model is a set of two first-order differential equations that describe the membrane dynamics of a spiking neuron. The depolarisation is modelled by an instantaneous calcium current, and the hyperpolarisation by a slow potassium current and a leak current. The membrane potential v_i and potassium activation w_i of neuron i ($i, j = 1, 2$) is described by:

$$\dot{v}_i = f(v_i, w_i) - \bar{g} s_j (v_i - v_s), \tag{1}$$

$$\dot{w}_i = h(v_i, w_i). \tag{2}$$

Here v_s is the inhibitory reversal potential, and $\bar{g}$ and s_j are the maximal synaptic conductance and the synaptic gating, respectively, constituting the total inhibitory conductance $\bar{g} s_j$ from neuron j to neuron i.

Function $f(v_i, w_i)$ describes the membrane currents of a single cell:

$$f(v_i, w_i) = -g_{\mathrm{Ca}} m_\infty(v_i)(v_i - v_{\mathrm{Ca}}) - g_{\mathrm{K}} w_i (v_i - v_{\mathrm{K}}) - g_{\mathrm{L}}(v_i - v_{\mathrm{L}}) + I. \tag{3}$$

The currents include a constant current I, and three ionic currents: an instantaneous calcium current, a potassium current, and a leak current, with respective reversal potentials v_{Ca}, v_{K}, and v_{L}, as well as maximum conductances g_{Ca}, g_{K}, and g_{L}. The function $h(v_i, w_i)$ models the kinetics of the potassium gating variable w_i, and is given by

$$h(v_i, w_i) = \frac{w_\infty(v_i) - w_i}{\tau_w}\,. \tag{4}$$

The steady-state activation functions m_∞ and w_∞ as well as the default model parameters are described in the **Supplementary Material S1**.

The dynamics of the synaptic interactions between the neurons are governed by a synaptic gating variable s_i and a depression variable d_i:

$$\dot{d}_i = \begin{cases} (1 - d_i)/\tau_a \text{ if } v_i < v_\theta, \\ -d_i/\tau_b \text{ if } v_i > v_\theta, \end{cases} \tag{5}$$

$$\dot{s}_i = \begin{cases} -s_i/\tau_\kappa \text{ if } v_i < v_\theta, \\ (d_i - s_i)/\tau_\gamma \text{ if } v_i > v_\theta. \end{cases} \tag{6}$$

Variable d_i describes a firing rate dependent depletion mechanism that governs the amount of depression acting on the synapse. The model is agnostic with respect to the exact mechanism of this depletion, be it pre- or post-synaptic. When the voltage is below firing threshold, depression variable d_i recovers with time constant τ_a, while synaptic variable s_i decays with time constant τ_κ. Because synaptic depression occurs on a much slower timescale than synaptic inhibition, we assume $\tau_d \gg \tau_\kappa$. When the voltage is above firing threshold, variable d_i decays to zero with τ_b, while s_i quickly approaches the respective value of d_i. Since τ_γ is the shortest time constant of the system with $\tau_\gamma \ll 1$, we can assume that whenever $v > v_\theta$ we can we have $s_i = d_i$. The equations for the depression model were adapted from the Bose et al. [3] model. These equations are a mathematically tractable simplification of the established phenomenological depression model previously described by Tsodyks and Markram [4].

When the cells are uncoupled ($\bar{g} = 0$), the membrane dynamics are determined by the cubic v-nullcline $v_\infty(v_i)$ and the sigmoid w-nullcline $w_\infty(v_i)$, satisfying $\dot{v}_i = 0$ and $\dot{w}_i = 0$, respectively. The two curves intersect along the middle branch of v_∞, creating an unstable fixed point $p_f = (v_f, w_f)$ with a surrounding stable limit cycle of period $T = T_{act} + T_{inact}$ (fig. 1A). Here T_{act} is the amount of time the cell spends in the active state when $v > v_\theta$, while T_{inact} is the time it spends in the silent state when $v < v_\theta$. Trajectories along that limit cycle have the familiar shape of the action potential (fig. 1B). The trajectory of an action potential can be dissected into four phases: (1) a silent phase, (2) a jump up, (3) an active phase, and (4) a jump down [see e.g. 5]. During the silent phase the trajectory evolves along the left branch ($v_i < v_\theta$) of the cubic v-nullcline. Once the trajectory reaches the local minimum of v_∞, it "jumps up" to the right branch ($v_i > v_\theta$), crossing the firing threshold v_θ. During the active phase the trajectory then evolves along the right branch of the cubic until it arrives at the local maximum, where it "jumps down" to the left branch commencing a new cycle.

The two-cell network model is numerically integrated using an adaptive step-size integrator for stiff differential equations implemented with XPPAUT [6] and controlled through the Python packages SciPy [7] and PyXPP [8]. The following mathematical analysis is performed on the equations of a single cell. Unless required for clarity, we will therefore omit the subscripts i, j from here on.

3 RESULTS

3.1 Anti-phase burst solutions

Short-term synaptic depression of inhibition in a half-centre oscillator acts as a *burst termination* mechanism [9] and is known to produce $n - n$ anti-phase burst solutions of varying period. Such $n - n$

solutions consist of cells firing bursts of n spikes in alternation. Figure 2A shows the timecourse of a typical $4-4$ burst. While one cell is firing a burst it provides an inhibitory conductance to the other cell, preventing it from firing. Therefore, at any given moment one cell is spiking while the other is inhibited. Consistent with Bose and Booth [2] we will refer to the currently firing cell as "free" and we will call the inhibited cell "quiet". Additionally, we will distinguish between two phases of a $n-n$ solution: We will refer to the burst duration of a cell as the "free phase", which is the time between the first spike and the last spike in a burst. And we will call the remaining duration of a cycle, when a cell is not spiking, the "quiet phase".

With each action potential of the free cell, short-term depression leads to a step-wise decrease of d, and consequently of s (fig. 2B). If d depresses faster at spike time than it can recover in the inter-spike-intervals (ISIs), the total synaptic conductance $\bar{g}s$ will eventually become sufficiently small to allow for the quiet cell to be released and start firing, thus inhibiting the previously free cell. While a cell is quiet its depression variable can recover. Once the quiet cell becomes free again its synaptic inhibition will be sufficient to terminate the burst of the previously free cell and commence a new cycle. As previously demonstrated by Bose and Booth [2], in a two-cell reciprocally inhibitory network with synaptic depression the coupling strength $\bar{g}$ determines the type of $n-n$ solution. Increasing $\bar{g}$ produces higher $n-n$ burst solutions with more spikes per burst and a longer cycle period. Figure 3 shows numerically stable $n-n$ solutions for varying values of $\bar{g}$. For small values of $\bar{g}$ the network produces anti-phase spiking $1-1$ solutions. As $\bar{g}$ is increased the network generates solutions of increasing n, that is $2-2$, $3-3$, and $4-4$. When $\bar{g}$ is sufficiently large (bottom of fig. 3), one of the cells continuously spikes at its uncoupled period T while the other cell remains fully suppressed. Depending on the initial conditions either of the two cells can become the suppressed cell, which is why the suppressed solution is numerically bistable.

Branches of numerically stable $n-n$ solutions and their associated limit cycle period for varying values of $\bar{g}$ are depicted in fig. 4A (see **Supplementary Material S2** for algorithm description). Not only do higher $n-n$ solutions branches require stronger coupling $\bar{g}$, but also within $n-n$ branches the period increases with $\bar{g}$. In line with Bose and Booth [2] we find small overlaps between solution branches indicating numerical bistability, for example such as between the $2-2$ and $3-3$ solution branches. Branches of higher $n-n$ burst solutions occur on increasingly smaller intervals of $\bar{g}$, for instance is the $\bar{g}$ interval of the $5-5$ branch shorter than that of the $4-4$ branch and so on. The interval between the $5-5$ branch and the suppressed solution (region between dotted lines in fig. 4A) not only contains even higher numerically stable $n-n$ solutions, such as $11-11$ bursts, but also other non-symmetric $n-m$ solutions as well irregular, non-periodic solutions. However, the analysis in the following sections will only be concerned with the numerically stable and symmetric $n-n$ solutions.

3.2 Mathematical analysis of two-cell network

The goal of the following mathematical analysis is to reduce the complexity of the eight-dimensional system to some easily tractable quantity. As we will see later this quantity is the value of the depression variable d of either of the two cells. We will construct the solution of d in a piecewise manner from one spike to the next, first during the free phase, and then during the quiet phase. This construction will require two assumptions about the membrane and synaptic dynamics. The first assumption states that during a burst the free cell fires at its uncoupled period T, which simplifies the construction of the solution of d. The second assumption states that once the inhibitory conductance acting on the quiet cell drops below a critical threshold, the cell is immediately released and fires. The second assumption is necessary to predict the release time of the quiet cell, which allows us to model the recovery of d during the quiet phase. In other words, the second assumption requires that the release of the quiet cell from inhibition depends only on the timecourse of the inhibition, and not on the membrane dynamics of the quiet cell. Both assumptions can be observed in coupled relaxation-oscillator types of neurons such as the Morris-Lecar model we use, and will be numerically verified below. Both assumptions were first explored in [2] to derive algebraic conditions that guarantee the periodicity of the depression variable for different $n-n$ solutions. However here we will use these assumptions to construct a Poincaré map of d, which will provide a geometric intuition for the dynamics of the full two-cell network and its dependence on model parameters.

Our first assumption about the model states that the free cell fires at its uncoupled period T, that is, during the free phase of a burst we have $ISI = T$. Solution profiles in fig. 3 suggest that the ISIs are indeed approximately constant. We can further numerically confirm this observation by capturing

the ISIs of the stable solutions from the bifurcation diagram in fig. 4A. In addition to ISIs, Figure 4B also shows inter-*burst* intervals (IBIs), which correspond to the time interval between the last spike of the burst and the full cycle period, and which lie in the quiet phase of the burst. IBIs lie on multiple branches, each branch associated with a stable $n-n$ solution, and are monotonically increasing with $\bar{g}$. In contrast, ISIs are calculated from the spikes within the free phase and do not vary significantly with $\bar{g}$, but are approximately $ISI \approx T$, affirming our first assumption. Assuming $ISI = T$ allows us to ignore the non-linear membrane dynamics during the free phase, and to construct the evolution of the synaptic variables iteratively from spike to spike. Assuming $ISI = T$ seems reasonable given that inhibition acting on the quiet cell decays exponentially to zero on a much shorter timescale than the duration of the ISI, and therefore, once the quiet cell is released its trajectory quickly approaches the spiking limit cycle.

Our second assumption states that the quiet cell is released and spikes as soon as inhibition from the free cell drops below a constant threshold. We will now define such a "release condition" by exploiting the discrepancy in timescales between the fast membrane dynamics, and the slower synaptic dynamics. Let us first consider the dynamics of a single Morris-Lecar neuron. We fix the synaptic variable that acts on the cell by setting $s = 1$, which also makes the applied synaptic conductance $\bar{g}s$ constant. Recall from fig. 1A that in case of a single uncoupled cell ($\bar{g}s = 0$), the v- and w-nullclines intersect at some unstable fixed point $p_f = (v_f, w_f)$, while trajectories revolve around a stable spiking limit cycle. Increasing $\bar{g}s$ moves the cubic v_∞ with the ensuing unstable fixed point p_f down the sigmoid w_∞ in the $(v-w)$-plane (fig. 5). When $\bar{g}s$ is large enough, the fixed point p_f becomes stable, attracting all previously periodic trajectories. There exists a unique value $\bar{g}s = g^\star$ when p_f changes stability and the stable limit cycle vanishes. Thus, when a constant inhibitory conductance is applied, $\bar{g}s < g^\star$ acts as a necessary condition for a cell to spike. In contrast, when $\bar{g}s > g^\star$ inhibition is strong enough to prevent a cell from spiking [2].

Now let us analyse the nullclines of the quiet cell when the two cells are coupled via synaptic inhibition with depression. Let $\bar{g}s$ here denote the total synaptic conductance which acts on the quiet cell and is produced by the free cell, and let p_f be the fixed point associated with the quiet cell. At the start of the burst of the free cell we have $\bar{g}s > g^\star$ and p_f is stable. When the free cell spikes, $\bar{g}s$ peaks (**??**), and the v-nullcline with the ensuing stable p_f move down the w-nullcline. Then in between spikes $\bar{g}s$ decays exponentially (eq. (6)) causing the v-nullcline and p_f to move up the w-nullcline while attracting trajectories of the quiet cell. Once depression causes the synaptic conductance to become small enough to satisfy $\bar{g}s < g^\star$ and the quiet cell is released, fixed point p_f becomes unstable allowing the quiet cell to fire. If the trajectory of the quiet cell remains sufficiently close to the stable p_f at the time when it changes stability, then $\bar{g}s < g^\star$ acts as a release condition that is not only necessary, but also sufficient for firing of the quiet cell. In this case the release of the quiet cell occurs precisely when

$$\bar{g}s = g^\star \tag{7}$$

is satisfied.

Whether the (v, w)-trajectory of the quiet cell can remain close enough to p_f to make eq. (7) sufficient for firing depends largely on the coupling strength $\bar{g}$ and the timescale disparity between membrane dynamics and synaptic dynamics [2]. It is straightforward to test our assumption of a release condition by numerically integrating the full system of ODEs and calculating the time interval between the first spike of the quiet cell and the time when $\bar{g}s$ first crosses $g^\star$. We will call this time interval the "release delay". If our assumption holds, we would expect an approximately zero release delay. Figure 6 shows the numerically computed graph of the release delay for varying $\bar{g}$. The graph shows three distinct branches, next to each branch we also plot the timecourse of a corresponding sample solution of the total synaptic conductance $\bar{g}s$ of both cells. For the rightmost branch where $\bar{g} > 0.592\ \mathrm{mS/cm^2}$ the release delay is approximately zero. Here the first spike of the quiet cell can be accurately predicted by the release condition in eq. (7). The leftmost and middle branches for $\bar{g} < 0.592\ \mathrm{mS/cm^2}$ show a release delay greater than zero, the quiet cell does not immediately fire when the release condition is first satisfied, and eq. (7) does not accurately predict the release of the quiet cell. The leftmost and middle branches contain $1-1$ and $2-2$ solutions respectively. In both cases the coupling $\bar{g}$ is not sufficiently strong to allow trajectories of the quiet cell to be close enough to p_f to guarantee spiking once $\bar{g}$ crosses $g^\star$. Note that in the middle branch $\bar{g}s$ crosses $g^\star$ twice, and only after the second crossing does the quiet cell fire. The following map construction relies on the assumption that the release condition in eq. (7) can accurately predict the release time of the

quiet cell. Given our model parameters this is only possible for sufficiently large $\bar{g} > 0.592\ \mathrm{mS/cm^2}$. For completeness, however, we will also consider values $\bar{g} < 0.592\ \mathrm{mS/cm^2}$ in the following analysis, bearing in mind that in this parameter range our map will not be accurate.

In summary: For $\bar{g} > 0.592\ \mathrm{mS/cm^2}$ the release condition is sufficient to predict when the quiet cell is released. Due to the symmetry of $n-n$ solutions the release occurs at exactly half the period of the full cycle, that is at $P/2$. The release time therefore uniquely determines the type of $n-n$ solution. Furthermore, computation of the release time does not depend on the membrane nor the synaptic dynamics of the quiet cell. Instead, the solution of the synaptic variable s of the free cell is sufficient to predict when $\bar{g}s = g^*$ is satisfied. Finally, s is solely determined by the evolution of the depression variable d of the free cell. Constructing a solution of d during the free phase of either cell will therefore uniquely determine the solution of the full eight-dimensional network. However, finding the solution d requires us to know the initial value $d(0)$ at the start of a cycle at $t = 0$. In the next section we will construct a scalar return map that tracks these initial values $d(0)$ from cycle to cycle of stable $n-n$ solutions.

3.3 Construction of the scalar Poincaré map

In this section we construct the scalar Poincaré map $\Pi_n : d^\star \mapsto d^\star$. Here the discrete variable $d^\star$ tracks the values of the continuous depression variable d at the beginning of each $n-n$ burst. The map Π_n therefore describes the evolution of d, of either of the two cells, from the beginning of one cycle to the beginning of the next cycle. To simplify the map construction we will assume that a free cell fires exactly n times before it becomes quiet. Later we will relax this assumption. We will construct Π_n by evolving d first during the free phase and then during the quiet phase of the $n-n$ limit cycle. First, let us give explicit definitions of the free and quiet phases. A schematic illustration of both phases is given in fig. 7.

Suppose that at $t = 0$ cell 1 becomes free with some initial $d(0)$. Cell 1 then fires n spikes at the uncoupled period $T = T_{act} + T_{inact}$. Let $s(t)$ and $d(t)$ be the corresponding solutions of the synaptic and depression variables of cell 1. After n spikes the total conductance $\bar{g}s(t)$ acting on the quiet cell 2 has decayed sufficiently to satisfy the release condition (7), that is at some time $t = (n-1)T + \Delta t$, where $\Delta t < T_{inact}$, we have $\bar{g}s(t) = g^\star$. Cell 2 is then released and prevents cell 1 from further spiking. Here Δt is the time between the last spike of cell 1 and the first spike of cell 2 [2]. Once released, cell 2 also fires n spikes until cell 1 becomes free once again at the cycle period. Let P_n denote the full cycle period of a $n-n$ solution:

$$P_n = 2(n-1)T + 2\Delta t. \tag{8}$$

We can now define the free and quiet phases of cell 1 explicitly. The free phase is the time interval between the first and last spikes of the burst, that is for time $0 < t < (n-1)T$. During the free phase of cell 1, the quiet cell 2 is inhibited sufficiently strong to prevent it from firing, hence $\bar{g}s > g^\star$. The quiet phase of cell 1 is the remaining duration of the cycle when the cell is not firing, that is for $(n-1)T < t < 2(n-1)T + 2\Delta t$.

Note that only the quiet phase depends on Δt which will play a central role in the construction of Π_n. From eq. (8) Δt can be be computed as

$$\Delta t = \frac{1}{2}P_n - (n-1)T. \tag{9}$$

We can use eq. (9) and the numerically computed bifurcation diagram of the period for stable $n-n$ solutions in fig. 4A to obtain the graph of Δt as a function of $\bar{g}$ (fig. 8). Each continuous branch of Δt is monotonically increasing and corresponds to a $n-n$ burst: Stronger coupling $\bar{g}$ increases the total synaptic conductance $\bar{g}s$ that acts on the quiet cell, thus delaying its release. It is easy to see that for any n-branch we have $\Delta t < T$: Once Δt crosses T, the free cell can "squeeze in" an additional spike and the solutions bifurcate into a $(n+1)-(n+1)$ burst.

Distinguishing between the active and silent phases of a cycle allows us to describe the dynamics of the depression variable d explicitly for each phase. As can be seen from fig. 7C, during the active phase d depresses during the active phase of spikes and recovers during the inactive phases of spikes. In contrast, during the silent phase d only recovers and does not depress. Given the initial $d^\star = d(0)$ at the beginning of the cycle and the number of spikes in the free phase n, we can now construct the burst map Π_n. The

map

$$\Pi_n(d^\star) = Q_n\big(F_n(d^\star)\big) \tag{10}$$

is a composition of two maps. Map

$$F_n : d^\star \mapsto \Delta t \tag{11}$$

models the evolution of d in the free phase. F_n takes an initial value $d^\star$ and calculates the inter-burst-interval Δt. Map

$$Q_n : \Delta t \mapsto d^\star \tag{12}$$

models the recovery of d in the quiet phase. Given some Δt map Q_n computes $d^\star$ at the start of the next cycle.

Our aim in the following analysis is to elucidate the properties of Π_n and to understand the structure of its parameter space by exploring how the stable and unstable fixed points of Π_n are created. To that effect it will be useful to include not only positive, but also negative values of $d^\star$ to the domain of Π_n. But it is important to add that values $d^\star < 0$ are biologically impossible as the depression variable models a finite pool of neurotransmitters, and therefore must be positive. Because Π_n maps first from $d^\star$ to Δt, and then back to $d^\star$, we will also consider negative values of Δt, interpreting them as $n-n$ solutions with partially overlapping bursts. As will become evident, $\Delta t < 0$ is only a formal violation of the biological realism of the map Π_n, as numerically stable $n-n$ solutions of the full system of ODEs only exist for $\Delta t > 0$.

We start the construction of Π_n by first considering the free phase and building the map F_n. At each spike time t_k where $d(t_k) = d_k$, variable d decays first for the duration of the active phase of the spike for T_{act}, as described by the solution to eq. (5). At $t = t_k + T_{act}$ we have

$$d(t_k + T_{act}) = d_k e^{-T_{act}/\tau_b}. \tag{13}$$

The depression variable then recovers during the inactive phase of the spike until t_{k+1}, where for $0 < t < T_{inact}$ we get

$$d(t_{k+1}) = 1 - (1 - d_k e^{-T_{act}/\tau_b})e^{-t/\tau_a}. \tag{14}$$

By substituting $t = T_{inact}$ we can build a linear map that models the depression of d from spike time t_k to the subsequent spike time t_{k+1} during the free phase:

$$d_{k+1} = \lambda\rho d_k + (1-\rho), \tag{15}$$

where to keep the notation simple we let

$$\lambda = \exp(-T_{act}/\tau_b), \tag{16}$$

$$\rho = \exp(-T_{inact}/\tau_a). \tag{17}$$

Given constant T_{act} and T_{inact}, parameter λ determines how much the synapses depresses during the active phase of the spike, while ρ determines how much it recovers during the inactive phase. Since $0 < \lambda, \rho < 1$, map eq. (15) is increasing and contracting, with a fixed point at

$$d_s = \frac{1-\rho}{1-\lambda\rho}, \tag{18}$$

where $0 < d_s < 1$. The value d_s is the maximum depression value that can be observed in the suppressed solution where the active cell fires at its uncoupled period T (see fig. 3E). Using the release condition in eq. (7) allows us to derive the value of the the minimum coupling strength that will produce the full suppressed solution, denoted as $\bar{g}_s$. Solving eq. (6) for $s(t)$ with $t = T$ and setting the initial value $s(0) = d_s$ gives

$$\bar{g}_s d_s e^{-T/\tau_\kappa} = g^\star. \tag{19}$$

By further substituting the definition of d_s in (18) and rearranging, we can write $\bar{g}_s$ as a function of λ and ρ:

$$\bar{g}_s(\lambda,\rho) = g^\star e^{T/\tau_\kappa}\frac{1-\lambda\rho}{1-\rho}. \tag{20}$$

Note that the above dependence of $\bar{g}_s$ on λ is linear and monotonically decreasing. Increasing λ reduces the strength of the depression of the free cell. This in turn allows the free cell to fully suppress the quiet cell at smaller values of $\bar{g}$.

Solving (15) gives us the linear map $\delta_n : d^\star \mapsto d_n$, that for some initial $d^\star$ computes the depression at the nth spike time, $d_n = d(t_n^-)$:

$$\delta_n(d^\star) = (\lambda\rho)^{n-1}d^\star + (1-\rho)\sum_{i=0}^{n-2}(\lambda\rho)^i. \tag{21}$$

Since $\lambda < 1$, function δ_n is a linearly increasing function of $d^\star$ with a fixed point at d_s for all n. Having identified d after n spikes, we can now use the release condition $\bar{g}s = g^\star$ (eq. (7)) to find Δt. After the last spike of the free phase at time $t_n = (n-1)T$ the synapse variable s has the value of d for the duration of T_{act}, which is given by $\delta_n(d^\star)\lambda$. s then decays exponentially for $\Delta t < T_{inact}$. Solving eq. (6) (case $v < v_\theta$) with initial condition $s(0) = \delta_n(d^\star)\lambda$ yields:

$$s(\Delta t) = \delta_n(d^\star)e^{-\Delta t/\tau_\kappa}. \tag{22}$$

Substituting $s(\Delta t)$ into s of the release condition (eq. (7)) gives then

$$\bar{g}\delta_n(d^\star)e^{-\Delta t/\tau_\kappa} = g^\star. \tag{23}$$

Our assumption of the release condition guarantees that the quiet cell 2 spikes and becomes free when $\bar{g}s - g^\star$ crosses zero. Solving eq. (23) for Δt allows us to compute the inter-spike-interval as a function of $d^\star$, which defines our map F_n:

$$F_n(d^\star) := \tau_\kappa \ln\left(\frac{\bar{g}}{g^\star}\delta_n(d^\star)\right) = \Delta t. \tag{24}$$

Figure 9A shows F_n for various n, which is a strict monotonically increasing function of $d^\star$ as well as $\bar{g}$. Larger values of $d^\star$ and $\bar{g}$, respectively, cause stronger inhibition of the quiet cell, and therefore prolong its release time and the associated Δt. Map F_n is defined on $d^\star > d_a$, where d_a is a vertical asymptote found by solving $\delta_n(d^\star) = 0$ in eq. (21) for $d^\star$, which yields

$$d_a(n) = -\frac{(1-\rho)\sum_{i=0}^{n-2}(\lambda\rho)^i}{(\lambda\rho)^{n-1}} \leq 0\,. \tag{25}$$

We now turn to the construction of map Q_n, which describes the recovery of the depression variable during the quiet phase. As we have identified earlier, the recovery in the quiet phase of a $n-n$ solution is of duration $2\Delta t + (n-1)T$. Substituting that into the solution for $d(t)$ (**??**) with the initial condition $d(0) = \delta_n(d^\star)$ yields the map Q_n:

$$Q_n(\Delta t) := 1 - (1 - \lambda\delta_n(d^\star))e^{-(2\Delta t + (n-1)T)/\tau_d}. \tag{26}$$

Given Δt, we can find $\delta_n(d^\star)$ by rearranging the release condition in eq. (23):

$$\delta_n(d^\star) = \frac{g^\star}{\bar{g}}e^{\Delta t/\tau_s}. \tag{27}$$

Map Q_n is shown in fig. 9B for various values n. Note that Q_n is monotonically increasing as larger values Δt imply a longer recovery time, and hence Q_n grows without bound. All curves Q_n intersect at some $\Delta t = \tau_s \ln[\bar{g}/(g^\star\lambda)]$ where

$$Q_n\left[\tau_s \ln\left(\frac{\bar{g}}{g^\star\lambda}\right)\right] = 1. \tag{28}$$

As we will show in the next section, all fixed points of the full map Π_n occur for $d^\star < 1$. We will therefore restrict the domain of Q_n to $(-\infty, \ln[\bar{g}/(g^\star\lambda)]\tau_s)$ and the codomain to $(-\infty, 1)$. Additionally, while values $\Delta t > T$ will be helpful in exploring the geometry of Π_n, recall from fig. 8 that in the flow

system all $n-n$ solutions bifurcate into $(n+1)-(n+1)$ solutions exactly when $\Delta t = T$, and we will address this concern in the last part of our map analysis.

Having found F_n and Q_n, we can now construct the full map $\Pi_n(d^\star) = Q_n\big(F_n(d^\star)\big)$:

$$\Pi_n(d^\star) = 1 - \frac{\rho^{n-1} g^{\star\tau}}{\bar{g}^\tau} \delta_n^{-\tau}(d^\star)\big(1 - \lambda\delta_n(d^\star)\big), \tag{29}$$

where we substituted $\tau = 2\tau_s/\tau_d$. Since d is the slowest variable of the system and $\tau_d \gg \tau_s$, we will also assume $\tau < 1$. Figure 10A depicts Π_n for various n. Intersections of Π_n with the diagonal are fixed points of the map. Figure 10B shows Π_2 with $n = 2$. Varying the synaptic strength $\bar{g}$ moves the curves Π_n up and down the $(d^\star, \Pi_n)$-plane. For $\bar{g} < 0.03\ \mathrm{mS/cm^2}$ map Π_2 has no fixed points. As $\bar{g}$ is increased to $\bar{g} \approx 0.03\ \mathrm{mS/cm^2}$, curve Π_2 coalesces with the diagonal tangentially. When $\bar{g} > 0.03\ \mathrm{mS/cm^2}$, a pair of fixed points emerge, one stable and one unstable fixed point, indicating the occurrence of a fold bifurcation of maps.

From eq. (29) it is evident that Π_n is monotonically increasing with respect to $\bar{g}$ and also $d^\star$:

$$\frac{\mathrm{d}\Pi_n}{\mathrm{d}\bar{g}} > 0, \tag{30}$$

$$\frac{\mathrm{d}\Pi_n}{\mathrm{d}d^\star} > 0, \tag{31}$$

and in the following sections we will heavily rely on this monotonicity property of Π_n. Just as F_n, curves Π_n spawn at the asymptote d_a (eq. (25)), and because

$$\lim_{\bar{g}\to\infty} \Pi_n = 1 \text{ for all } n, \tag{32}$$

fixed points of Π_n lie in $(d_a, 1)$.

3.4 Existence and stability of fixed points

We introduce the fixed point notation $d_f^\star$ with $\Pi_n(d_f^\star) = d_f^\star$. The existence of fixed points $d_f^\star$ for $\bar{g}$ sufficiently large can be shown from the strict monotonicity of Π_n with respect to $\bar{g}$ and $d^\star$ (eqs. (30) and (31)), as well as the fact that the slope of Π_n is monotonically decreasing,

$$\left(\frac{\mathrm{d}}{\mathrm{d}d^\star}\right)^2 \Pi_n < 0. \tag{33}$$

In the limit $d^\star \to d_a$ the value of Π_n decreases without bound for any $\bar{g} > 0$. In the limit $\bar{g} \to 0$, Π_n also decreases without bound, but as $\bar{g} \to \infty$ values of Π_n approach 1. It follows from eq. (30) and the intermediate value theorem that for some $\bar{g}$ large enough Π_n intersects the diagonal. Moreover, because Π_n and its slope are monotonic with respect to $d^\star$, there exists some critical fixed point $(d_b^\star, \bar{g}_b)$ where Π_n aligns with the diagonal tangentially with

$$\Pi_n(d_b^\star; \bar{g}_b) = d_b^\star, \tag{34}$$

$$\frac{\mathrm{d}}{\mathrm{d}d^\star}\Pi_n(d_b^\star; \bar{g}_b) = 1. \tag{35}$$

Equations (30) and (33) constitute the non-degeneracy conditions for a codimension-1 fold bifurcation of maps, indicating that in a neighbourhood of $(d_b^\star, \bar{g}_b)$ map Π_n has the topological normal form described by the graph of

$$x \mapsto \beta + x - x^2, \tag{36}$$

with a stable and unstable fixed point $x = \pm\sqrt{\beta}$, and slopes $\mathrm{d}x/\mathrm{d}\beta = \mp(2\sqrt{\beta})^{-1}$, respectively.

3.5 Fold bifurcations

Fixed points of Π_n satisfy the fixed point equation

$$\Phi_n(d^\star; \bar{g}) = 0, \tag{37}$$

where

$$\Phi_n(d^\star, \bar{g}) := \Pi_n(d^\star, \bar{g}) - d^\star. \tag{38}$$

As we have already shown, for $\bar{g} > \bar{g}_b(n)$ solutions to eq. (37) exist in pairs of stable and unstable fixed points. Solving eq. (37) explicitly for $d^\star$ it not trivial, but solving for $\bar{g}$ is straightforward and given by $\bar{g} = G_n(d^\star)$, where

$$G_n(d^\star) := g^\star \left(\frac{\rho^{n-1}\delta_n^{-\tau}(d^\star)(1 - \lambda\delta_n(d^\star))}{1 - d^\star} \right)^{1/\tau}. \tag{39}$$

Plotting $d^\star$ against $\bar{g}$ gives the fixed point curves, which are shown in fig. 11A. Note the typical quadratic shape of a fold bifurcation of maps. It is also evident that the fold bifurcations occur for increasingly smaller $\bar{g}$ as n is increased. Moreover, we can observe that unstable fixed points have negative values of $d^\star$ for $n > 1$.

Equation (39) also allows us to find the critical fixed point connected with the fold bifurcation, namely $\big(d_b^\star(n), \bar{g}_b(n)\big)$, which is the global minimum of $G_n(d_f^\star)$:

$$d_b^\star(n) = \operatorname{argmin} G_n(d_f^\star), \tag{40}$$

$$\bar{g}_b(n) = \min G_n(d_f^\star). \tag{41}$$

Function G_n is strictly monotonic on the respective intervals of $d_f^\star$ that correspond to the stable and unstable fixed points, that is

$$\frac{\mathrm{d}G_n}{\mathrm{d}d_f^\star} < 0, \text{ for } d_f^\star > d_b^\star(n) \text{ stable}, \tag{42}$$

$$\frac{\mathrm{d}G_n}{\mathrm{d}d_f^\star} > 0, \text{ for } d_f^\star < d_b^\star(n) \text{ unstable}, \tag{43}$$

which allows us to express the stable and unstable fixed points as the inverse of G_n on their respective intervals of $d_f^\star$. Because we are primarily interested in the stable fixed points, we define the stable fixed point function $d_f^\star = \phi_n(\bar{g})$ as

$$\phi_n(\bar{g}) := G_n^{-1}(d_f^\star) \text{ for } d_f^\star > d_b^\star(n). \tag{44}$$

Function $\phi_n(\bar{g})$ is also monotonic, and is therefore straightforward to compute numerically via root-finding. Here we use the Python package Pynverse [10] for that purpose.

Having found the stable fixed points $d_f^\star$ as a function of the coupling strength $\bar{g}$, we can now compute the associated cycle period. Recall that the period is given by eq. (8), which we can be written as a function of $\bar{g}$:

$$P_n(\bar{g}) = 2(n-1)T + 2F_n\big(\underbrace{\phi_n(\bar{g})}_{d_f^\star}, \bar{g}\big), \tag{45}$$

where map F_n (eq. (24)) calculates the inter-burst-interval Δt given a stable fixed point $d_f^\star = \phi_n(\bar{g})$. We plot the predicted period $P_n(\bar{g})$ versus the cycle period that was computed from numerically integrating the full system of ODEs in fig. 11B. For $n > 1$ our map Π_n accurately predicts the period. When laying out our assumptions in section 3.2, we have already predicted an inaccuracy for $n = 1$ (see fig. 6), since here $\bar{g}$ is not sufficiently strong to guarantee the validity of our release condition (eq. (7)).

It is evident from fig. 11A that ϕ_n is strictly increasing with $\bar{g}$. This property follows directly from the normal form of the fold bifurcation (eq. (36)), but can also be shown using implicit differentiation and the fixed point equation $\Phi_n(\phi_n(\bar{g}), \bar{g}) = 0$ in eq. (37). For $d_f^\star = \phi_n(\bar{g}) > d_b(n)$ we get:

$$\frac{\mathrm{d}\phi_n}{\mathrm{d}\bar{g}} = -\frac{\partial\Phi_n/\partial\bar{g}}{\partial\Phi_n/\partial d^\star} = \frac{\partial\Pi_n/\partial\bar{g}}{1 - \partial\Pi_n/\partial d^\star} > 0. \tag{46}$$

The inequality follows from $\partial\Pi_n/\partial\bar{g} > 0$ and the fact that $\partial\Pi_n/\partial d^\star < 1$ for $d^\star > d_b(n)$. Equation (46) allows us to explain why the period P_n increases with $\bar{g}$, as seen in fig. 11B. Differentiating P_n gives:

$$\frac{\mathrm{d}P_n}{\mathrm{d}\bar{g}} = 2\boldsymbol{\nabla}F_n(d_f^\star, \bar{g}) \cdot \begin{bmatrix} \partial\phi_n/\partial\bar{g} \\ 1 \end{bmatrix} > 0, \tag{47}$$

where the partial derivatives of $F_n(d_f^\star, \bar{g})$ are:

$$\frac{\partial F_n}{\partial d_f^\star} = \tau_s \frac{(\lambda\rho)^{n-1}}{\delta_n(d_f^\star)} > 0, \tag{48}$$

$$\frac{\partial F_n}{\partial \bar{g}} = \frac{\tau_s}{\bar{g}} > 0. \tag{49}$$

Equations (46) and (47) have an intuitive biological interpretation: Increasing the coupling strength between the neurons leads to overall stronger inhibition of the quiet cell, which delays its release and leads to a longer cycle period. The latter allows more time for the synapse to depress in the free phase and recover in the quiet phase, resulting in overall larger values of $d_f^\star$, that is weaker depression at the burst onset.

While fixed points of our Poincaré map predict the cycle period of the flow system excellently, its construction relies on the strong assumption that the free phase contains exactly n spikes. As is evident from fig. 11B this assumption is clearly violated in the flow system, as stable $n-n$ bursts exists only on certain parameter intervals of $\bar{g}$. In the last sub-section we will analyse the mechanisms that guide how the stable $n-n$ are created and destroyed, and use our previous analysis to derive the corresponding parameter intervals of $\bar{g}$ where such solutions exist.

3.6 Period increment bifurcations with co-existent attractors

Let $\bar{g}_+(n)$ and $\bar{g}_-(n)$ denote the left and right parameter borders on $\bar{g}$ where stable $n-n$ solutions exist. That is, as $\bar{g}$ is increased stable $n-n$ solutions are created at $\bar{g}_+(n)$ and destroyed at $\bar{g}_-(n)$. When $\bar{g}$ is reduced beyond $\bar{g}_+(n)$, $n-n$ solutions bifurcate into $(n-1)-(n-1)$ solutions, while when $\bar{g}$ is increased beyond $\bar{g}_-(n)$, $n-n$ solutions bifurcate into $(n+1)-(n+1)$ solutions. Let us briefly recap our observations regarding $\bar{g}_+(n)$ and $\bar{g}_-(n)$ from the numerical bifurcation diagram in fig. 11B. For $n > 1$ there are the following relations:

$$\bar{g}_+(n) < \bar{g}_-(n), \tag{50}$$

$$\bar{g}_+(n) < \bar{g}_+(n+1) \text{ and } \bar{g}_-(n) < \bar{g}_-(n+1), \tag{51}$$

$$\bar{g}_+(n+1) < \bar{g}_-(n), \tag{52}$$

$$\bar{g}_-(n+1) - \bar{g}_+(n+1) < \bar{g}_-(n) - \bar{g}_-(n). \tag{53}$$

Equations (50) and (51) are self-explanatory. Equation (52) formally describes occurrence of co-existence between stable $n-n$ and $(n+1)-(n+1)$ solutions. Equation (53) implies that the parameter interval on $\bar{g}$ of $n-n$ solutions decreases with n, in other words, bursts with more spikes occur on increasingly smaller intervals of the coupling strength. All of the above relations are reminiscent of the period increment bifurcations with co-existent attractors, first described for piecewise-linear scalar maps with a single discontinuity by Avrutin and colleagues [e.g. see 11, 12, 13, 11]. While our maps Π_n are fully continuous, the above observation suggests that a different piecewise-linear scalar map that captures the

period increment bifurcations of the full system might exist. We will explore what such a map might look like in the discussion.

Let us now find algebraic equations that will allow us to calculate the critical parameters $\bar{g}_+(n)$ and $\bar{g}_-(n)$ associated with the period increment bifurcations. Recall that the period P_n derived from the fixed points of Π_n is an increasing function of $\bar{g}$:

$$\frac{\mathrm{d}P_n}{\mathrm{d}\bar{g}} = 2\frac{\mathrm{d}F_n(\phi_n(\bar{g}),\bar{g})}{\mathrm{d}\bar{g}} > 0, \tag{54}$$

that is, as the coupling strength increases, it takes longer for the total synaptic conductance to fall below the value of the release conductance, which delays the release of the quiet cell, and Δt becomes larger. Once $\Delta t = T$, the free cell can produce another spike and the solution bifurcates into a $(n+1)-(n+1)$ solution. Note, however, that at $\bar{g}_+(n)$ the bifurcation into a $(n-1)-(n-1)$ does not occur when $\Delta t = 0$. Here the mechanism is different: A sufficient reduction of $\bar{g}$ causes the total synaptic conductance to drop below the release conductance in the *previous* ISI, which allows the quiet cell to be released one spike earlier.

Using the above reasoning we can now formulate the conditions for both bifurcations at $\bar{g}_+(n)$ and $\bar{g}_-(n)$. As in the previous sections, we will only restrict ourselves to the analysis of the stable fixed points given implicitly by $d_f^\star = \phi_n(\bar{g})$ (eq. (44)). At the right bifurcation border $\bar{g}_-(n)$ we have $\Delta t = T$, and after substituting our F_n-map (eq. (24)) this translates into

$$F_n(\phi_n(\bar{g}),\bar{g}) = T, \tag{55}$$

which lets us define a function

$$R_n(\bar{g}) := F_n(\phi_n(\bar{g}),\bar{g}) - T, \tag{56}$$

whose root is the desired right bifurcation border $\bar{g}_-(n)$. In case of the left bifurcation border at $\bar{g}_+(n)$ the release condition is satisfied just before the free cell has produced its nth spike, and after the depression variable has been reset $n-1$ times, which gives the condition

$$\bar{g}\delta_{n-1}\big(\phi_n(\bar{g})\big)e^{-T/\tau_s} = g^\star, \tag{57}$$

and can be rewritten as a function

$$L_n(\bar{g}) := \bar{g}\delta_{n-1}\big(\phi_n(\bar{g})\big)e^{-T/\tau_s} - g^\star, \tag{58}$$

whose root is $\bar{g}_+(n)$. Both R_n and L_n are increasing with respect to $\bar{g}$, which makes finding their roots numerically straightforward.

Figure 12 shows the period $P_n(\bar{g})$ as predicted by the fixed points of Π_n (eq. (45)) plotted on their respective intervals $\bar{g} \in [\bar{g}_+(n), \bar{g}_-(n)]$ (blue), as well as the cycle period acquired from numerical integration of the full system of ODEs (orange). Note that the width of $n-n$ branches decreases with n, which confirms the inequality in eq. (53). That is, bursts with more spikes occur on increasingly smaller intervals of $\bar{g}$, which can be interpreted as a lost of robustness with respect to the coupling strength of long-cyclic solutions. We also note the occurrence of bi-stability between pairs of $n-n$ and $(n+1)-(n+1)$ branches, which also confirms our initial observation in eq. (52).

As previously observed in fig. 11B our maps prediction of the cycle period is accurate for $n > 1$. Recall that our reduction assumptions required a sufficiently large coupling strength, which we numerically estimated to be $\bar{g} \approx 0.592\mathrm{mS/cm^2}$ in fig. 6. The mismatch in period for $1-1$ solutions, but also the mismatch in the left bifurcation border $\bar{g}_-(n=2)$ of the $2-2$ solution can be attributed to the violation of that assumption. However, even for branches of large $n-n$ solutions there is a mismatch between the bifurcation borders. Presumably our assumptions on the time scales of w and s dynamics do not hold here, and can only be captured by more complex approximations. Nevertheless, our map allows approximate extrapolation of the cycle period and the respective bifurcation borders where numerical integration of the ODEs would require a very small time step.

4 DISCUSSION

Synaptic depression of inhibition is believed to play an important role in the generation of rhythmic activity involved in many motor rhythms such as in leech swimming [14] and leech heart beat [15], and in the lobster pyloric system [16, 17]. In inhibitory half-centre CPGs, such as believed to be found in the struggling network of *Xenopus* tapdoles, synaptic depression can act as a burst termination mechanism, enabling the alternation of bursting between the two sides of the CPG [18]. Mathematical modelling can shed light on the underlying mechanisms that enable the generation of such anti-phase bursts, and help identify the components that control this rhythm allowing it to switch between different patterns.

To study the mechanisms of burst generation in half-centre CPGs we have analysed a neuronal model network that consists of a pair of inhibitory neurons that undergo a frequency dependent synaptic depression. When the strength of synaptic inhibition between the neurons is varied, such a simple network can display a range of different $n-n$ burst patterns. Using the timescale disparity between neuronal and synaptic dynamics, we have reduced the network model of eight ODEs to a scalar first return map Π_n of the slow depression variable d. This map Π_n is a composition of two maps, F_n and Q_n, that model the evolution of the depression during the free and quiet phases of $n-n$ solutions respectively. Both F_n and Q_n maps are constructed by using the dynamics of single uncoupled neurons. Fixed points of Π_n are created in pairs through a fold bifurcation of maps, where the stable fixed point correspond to stable $n-n$ burst solutions of the full two-cell system of ODEs. The results from our one-dimensional map match excellently with numerical simulation of the full network. Our results are in line with Brown's 1911 rhythmogenesis hypothesis, namely that synaptic depression of inhibition is a mechanism by which anti-phase bursting may arise.

We have studied $n-n$ solutions assuming that the synaptic coupling $\bar{g}$ between the two cells is symmetrical. However, Bose and Booth [2] have shown that asymmetrical coupling $(\bar{g}_1, \bar{g}_2)$ can result in network solutions of type $m-n$, where one cell fires m spikes, while the other n spikes. It is conceivable that our map construction can be extended to also capture such $m-n$ solutions. Remember, in the case of symmetrical coupling with $n-n$ solutions, the timecourse of the depression variables d_1 and d_2 were in anti-phase, and it was therefore sufficient to track only one of the two variables. To capture the full network dynamics in case of asymmetrical coupling one would also have to account for burst patterns of type $m-n$, where the solutions of the depression variables d_1 and d_2 are not simply time-shifted versions of each other. To do that, one could track the state of both variables by constructing a two-dimensional Poincaré map $\Pi(d_1, d_2)$. While geometrical interpretation of two-dimensional maps remains challenging, there exist a number of recent studies which have employed novel geometrical analysis methods to understand the dynamics of two-dimensional maps of small neuronal networks [19, 20, 21]. Generally speaking, our map construction approach is applicable to any small network, even with more than two neurons. As long as the network dynamics occur on separable timescales the main challenges to the map construction lie in identifying the slowest variables, and finding an appropriate, simplified description of their respective timecourses. In theory, the reduction approach can be also applied to neuronal systems with more than two timescales [e.g. see 22].

In tadpoles, struggling is believed to be initiated by an increase in the firing frequency of reciprocally inhibitory commisural interneurons, which has been hypothesised to lead to stronger synaptic depression of inhibition and result in the iconic anti-phase bursting [18]. It would therefore be interesting to study how varying the cell intrinsic firing period T could affect the network rhythm. While we have laid out the framework to perform such an investigation, due to the choice of neural model we have avoided varying T. Recall that T is a derived parameter in the Morris and Lecar [1] model, and can therefore not be varied in isolation of other model parameters. This makes verifying any analytical results from our map analysis via numerical integration of the ODEs difficult. A more abstract model such as the quadratic integrate-and-fire model [23] allows varying T independently of other model parameters, and could be more fitting in this scenario.

Our simulations of the network showed that $n-n$ solutions lose robustness as their period is increased. That is, solutions with a larger cycle period occur on increasingly smaller intervals of the coupling strength. We were able to replicate this finding by numerically finding the respective left and right borders of stable $n-n$ branches of fixed points of Π_n, and showing that the distance between these borders shrinks with n. We have also noted the resemblance of our bifurcation diagram to one where such $n-n$ branches are created via a period-increment bifurcation with co-existent attractors of scalar linear maps

with a discontinuity [24, 13]. It is worthwhile noting that the bifurcations of piecewise linear maps studied by Avrutin et al. and colleagues result from a "reinjection" mechanism, first described by Perez [25]. Here the orbit of a map performs multiple iterations on one side of the discontinuity, before jumping to the other side and being *reinjected* back into the initial side of the discontinuity. The stark difference of such a map to our map is that reinjection allows a *single* scalar map to produce periodic solutions of varying periods. In contrast, we rely on n different maps Π_n to describe the burst dynamics without explicitly capturing the period increment bifurcations. It is therefore conceivable that despite the complexity and non-linearity of the dynamics of our two-cell network, a single piecewise-linear map might be already sufficient to capture the mechanisms that shape the parameter space of the full system. In their discussion, Bose and Booth [2] briefly outline ideas about how such a linear map could be constructed.

In addition to stable $n-n$ solutions, the numerical continuation by Bose and Booth [2] also revealed branches of unstable $n-n$ solutions. While we have identified fold bifurcations of our burst map, we have not found corresponding bifurcations of the flow ODE system, and have generally ignored the significance of unstable map fixed points. However, the quadratic nature of the period bifurcation curve is reminiscent of a saddle-node on an invariance circle (SNIC) bifurcation, where the oscillation period lengthens and finally becomes infinite as a limit cycle coalesces with a saddle point. SNIC bifurcations have been studied in great detail [e.g. 26], and a next step would be to provide a rigorous explanation of not only the map dynamics, but also of the flow dynamics of the ODE system.

We have shown that when the strength of the maximum synaptic conductance is varied, synaptic depression of inhibition can enable our two-cell network to produce burst solutions of different periods. This result is in line with the idea that one role of synaptic depression in the nervous system may be to allow a finite size neuronal network to participate in different tasks by producing a large number of rhythms [2, 27, 18]. To change from one rhythm to another would only require a reconfiguration of the network through changes in synaptic coupling strength, which can occur through the process of learning. Thus short-term synaptic depression of inhibition may provide means for a network to adapt to environmental challenges without changing its topology, that is without the introduction or removal of neurons.

CONFLICT OF INTEREST STATEMENT

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

AUTHOR CONTRIBUTIONS

MO and CH contributed to conception and design of the study. MO performed numerical computation and analysis. All authors contributed to manuscript writing and revision.

FUNDING

This work was supported by the Wellcome Trust Doctoral Training Programme in Neural Dynamics, Grant no. 099699/Z/12/Z.

ACKNOWLEDGEMENTS

The first author thanks the Wellcome Trust for financial support of his Ph.D. study. We thank Alan Champneys for sharing his insights on non-continuous maps during the course of this research. We are also grateful to Alan Roberts and Stephen R. Soffe for their comments on earlier versions of the manuscript.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

FIGURE CAPTIONS

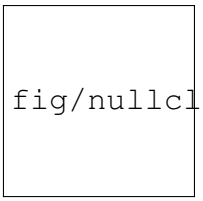

Figure 1. Periodic solution of relaxation-oscillator model neuron. $(\mathbf{A})$ Projection of limit cycle onto (v, w)-phase plane with v-nullcline (blue, v_∞) and w-nullcline (orange, w_∞). Unstable fixed point p_f is indicated by an orange dot. $(\mathbf{B})$ Corresponding voltage trace $v(t)$ of an action potential.

Figure 2. Solution profiles of a $4-4$ burst. $(\mathbf{A})$ Membrane potentials of cell 1 (v_1, blue), and cell 2 (v_2, orange). $(\mathbf{B})$ Synaptic variables d_1 (blue) and s_1 (grey) of cell 1.

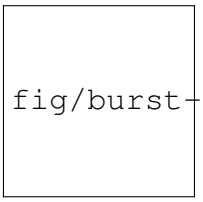

Figure 3. Voltage traces of both cells of numerically stable solutions for increasing values of the coupling strength $\bar{g}$ (increasing top to bottom).

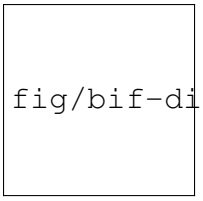

Figure 4. Numerically computed bifurcation diagrams of stable $n-n$ solutions for increasing coupling strength $\bar{g}$. $(\mathbf{A})$ Period of stable solutions. Dashed lines show the interval between the $5-5$ and the suppressed solutions, where higher period $n-n$ solutions occur on increasingly smaller intervals of $\bar{g}$. $(\mathbf{B})$ ISIs corresponding to $n-n$ solutions in (A). Long ISIs are associated with the quiet phase of a burst, short ISIs with the free phase. During the free phase, ISIs are of approximately constant duration T.

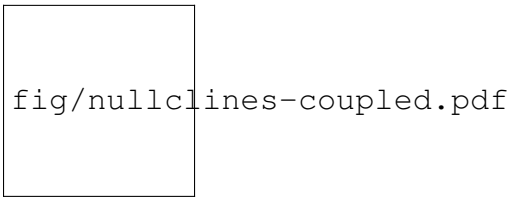

Figure 5. Nullclines v_∞ (blue) and w_∞ (orange) in the (v,w)-phase plane for different values of the total synaptic conductance $\bar{g}s$. For small $\bar{g}s < g^\star$, fixed point p_f is unstable (orange point). Larger values $\bar{g}s$ move v_∞ down in the (v,w)-plane until p_f changes stability (half orange, half blue point) at some critical total conductance value $\bar{g}s = g^\star$, and becomes stable (blue point) for $\bar{g} > g^\star$.

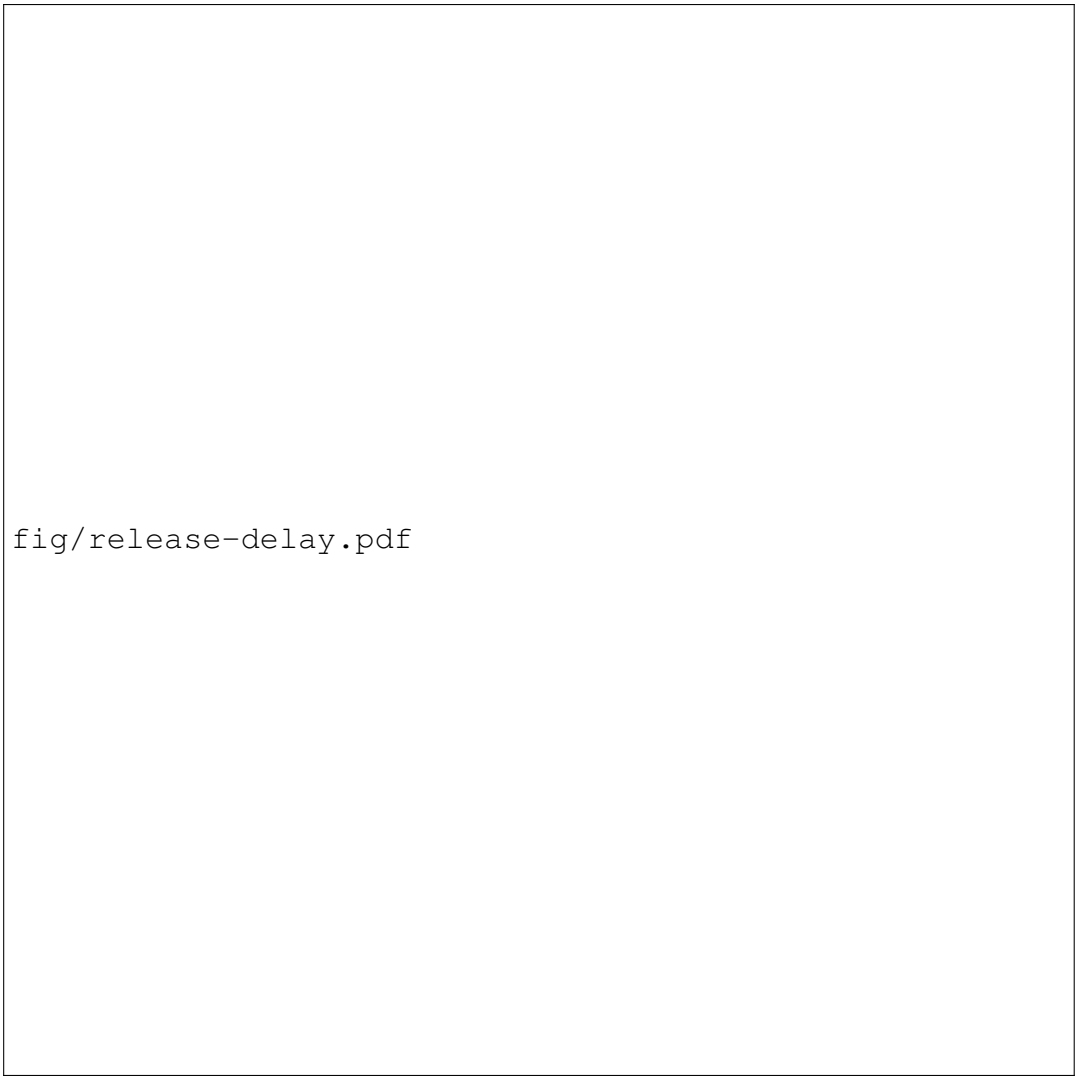

Figure 6. Numerically computed values of the release delay for varying $\bar{g}$. Each of the three branches (A, B, C) also shows the timecourse of the total synaptic conductance $\bar{g}s$ of a sample stable solution of both cells (blue and orange), as well as the release conductance $g^\star$ (dashed green line). $(\mathbf{A})$ Branch corresponding to the $1-1$ solution. Here the quiet cell only spikes after a significant release delay. $(\mathbf{B})$ Branch with a long release delay associated with a subset of $2-2$ solutions. Here the release condition is briefly satisfied after the first spike of cell 1. This does not cause firing of cell 2, which only occurs after the second spike of cell 1. $(\mathbf{C})$ Branch with $n-n$ solutions where release delay is approximately zero and the release condition is sufficient for firing of cell 2.

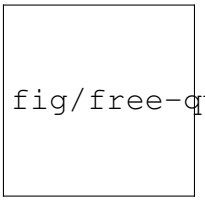

Figure 7. Schematic diagram of the free and quiet phases for a $3-3$ solution. $(\mathbf{A})$ Membrane potentials of cell 1 (v_1) and cell 2 (v_2). The grey patches depict inter-burst-intervals Δt. $(\mathbf{B})$ Total synaptic conductance of cell 1 ($\bar{g}s_1$) as it crosses the release conductance $g^\star$. $(\mathbf{C})$ Solution $d_1(t)$ of depression variable of cell 1, during free (blue) and quiet phases (orange).

Figure 8. Numerically computed bifurcation diagram of Δt for varying $\bar{g}$. Each continuous branch is associated with a stable $n-n$ burst solution. Increasing $\bar{g}$ increases Δt until the solutions bifurcate at $\Delta t \approx T$.

Figure 9. Maps F_n $(\mathbf{A})$ and Q_n $(\mathbf{B})$ for $\bar{g} = 0.6$ mS/cm^2 and $n = 1, 2, 3, 4$. Curves F_n intersect at d_s which is indicated by a dashed vertical line.

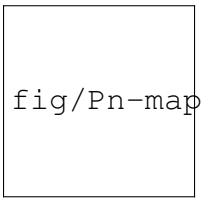

Figure 10. Map $\Pi_n : d^\star$. $(\mathbf{A})$ Π_n for $n = 1, 2, 3, 4$ at $\bar{g} = 0.6$ mS/cm^2. $(\mathbf{B})$ Π_2 with $n = 2$ for varying $\bar{g} \approx 0.01, 0.034, 0.3$ mS/cm^2. The identity function is illustrated by a diagonal line.

Figure 11. $(\mathbf{A})$ Fold bifurcation diagrams of stable (continuous curves) and unstable (dotted curves) fixed points of Π_n for varying n. $(\mathbf{B})$ Cycle periods computed from stable fixed points (blue), and the corresponding solution period from numerical integration of the system of ODEs (orange).

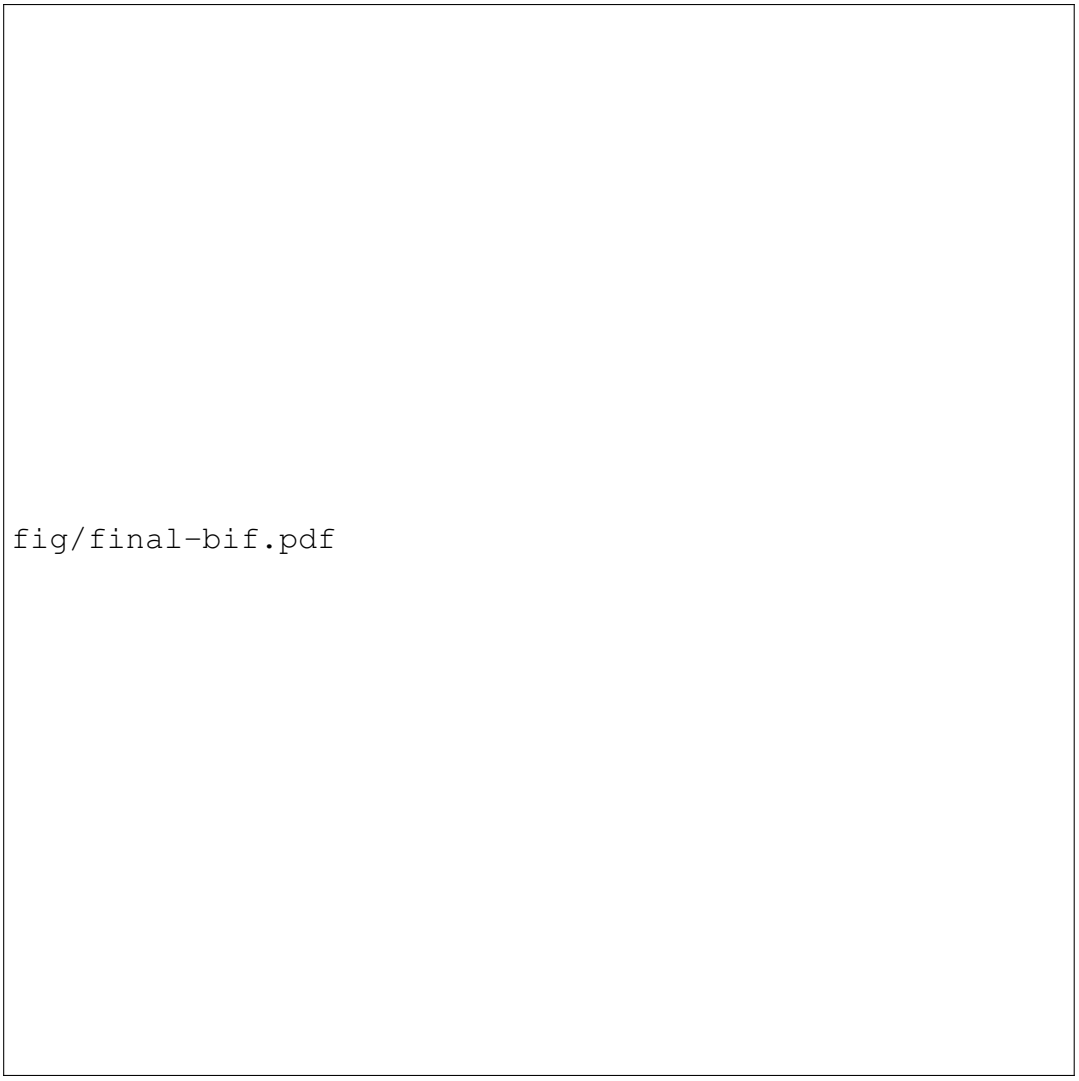

Figure 12. Bifurcation diagrams of stable $n - n$ solutions computed analytically from fixed points of Π_n and plotted on the respective intervals of $\bar{g} \in \left[\bar{g}_+(n), \bar{g}_-(n)\right]$ (blue), and computed from numerical integrations of the ODEs (orange).
